

Salesforce and Database Account Bidirectional Sync

Bidirectionally synchronizes account data between Salesforce and a database system like MySQL or a JDBC protocol supporting a DB system.

This service makes it fast to configure the fields to synchronize, how they map, and criteria for when to trigger the synchronization.

This service can trigger either using our polling mechanism or can be easily modified to work with Salesforce outbound messaging to better utilize Salesforce API calls.

This service leverages watermarking functionality to select only the most recent items are synchronized and batch to effectively process many records at a time. A database table schema is included to make testing this service easier.

Use Case

This service helps you create an online bidirectional sync of accounts between Salesforce and database instances with ability to specify filtering criteria.

The main behavior of this service fetches data for changes (new or modified accounts) that have occurred in Salesforce and database instances during a certain defined period of time. For those accounts that were identified as not present in the target instance, the integration triggers an insert or update operation on the existence of the object in the target instance taking the last modification of the object as the one that should be applied.
